Meta-Learning for Abstract Reasoning

1D-ARC Benchmark — Comprehensive Experimental Report

CSE559: Meta-Learning — From Few-Shot Classification to Learning to Learn
IIIT Delhi

March 2026

1 Introduction & Problem Setup

1.1 The 1D-ARC Benchmark

The **1D Abstraction and Reasoning Corpus** (1D-ARC) [2] is a simplified variant of Chollet's ARC benchmark [1], designed to test whether a model can infer transformation rules from a small number of input–output examples and generalize to an unseen input. Unlike standard few-shot classification where the label space is shared across tasks, each ARC task defines a *unique* transformation rule that must be discovered from scratch.

Task Definition

- **Dataset**: 901 tasks across 18 transformation types (move, copy, fill, flip, mirror, denoise, recolor, scale, etc.)
- **Each task**: 3 training (input → output) pairs + 1 test input
- **Input/Output**: 1D arrays of colored tokens (values 0–9), variable length (≤ 100)
- **Padding**: Dedicated token index 10 (value 0 is a valid color — black)
- **Vocabulary**: 11 tokens (0–9 = colors, 10 = padding); output classes: 10
- **Metrics**: **Exact Match (EM)** — 1 if the entire predicted sequence matches ground truth on every non-padding token, 0 otherwise. **Token Accuracy** — fraction of individual non-padding tokens correctly predicted.
- **Split**: 70/15/15 train/val/test (630/135/136 tasks)

1.2 Task Types (18 Categories)

The tasks span a diverse range of transformations requiring different levels of structural understanding:

Category	Tasks	Category	Tasks
Movement	Move 1/2/3/Dynamic px	Copying	Pattern Copy, Pattern Copy MC
Reflection	Flip, Mirror	Filling	Fill, Padded Fill, Hollow
Color	Recolor Count/Size/Cmp/OddEven	Noise	Denoise, Denoise MC
Scaling	Scale, Scale Dynamic		

1.3 Why Meta-Learning for ARC?

ARC is the **canonical few-shot reasoning benchmark** (Lecture 11). Each task is a standalone learning problem with only 3 training examples — exactly the meta-learning setup described in Lecture 5. Lecture 12 explicitly covers *MAML Applied to ARC*. For context, on the full 2D ARC benchmark: GPT-4 achieves 15%, o1 achieves 20%, o3 achieves 85%, and HRM achieves 40% (Lecture 11).

1.4 Formal Formulation (Lecture 5)

$$T_k = \{\mathcal{D}^k_{\text{train}}, \mathcal{D}^k_{\text{test}}\}, \quad \mathcal{D}^k_{\text{train}} = \{(\text{input}_i, \text{output}_i)\}_{i=1}^{3}, \quad \mathcal{D}^k_{\text{test}} = \{(\text{input}_{\text{test}}, ?)\} \tag{1}$$

This is a **3-shot** learning problem: the model must infer a transformation rule from 3 examples and apply it to a novel input. The meta-learner trains across hundreds of tasks so that it can rapidly adapt to any new transformation type at test time.

2 Novel Contributions Beyond Lectures

What We Did Beyond Course Material

1. **Hebbian Test-Time Adaptation (TTA) + MAML**: We combined biologically-inspired Oja's rule [9] online learning with MAML. The Hebbian layer adapts its weights on support examples *before* predicting the query, providing a complementary adaptation mechanism to gradient-based meta-learning. Standard meta-learning uses only gradient descent for adaptation; adding a Hebbian component introduces a second, biologically-motivated learning signal. This combination is novel and not covered in any lecture or standard meta-learning reference.

3 Shared Architecture

All methods (except ProtoNet, which uses a Transformer encoder) share a common CNN-based architecture. The meta-learning algorithm determines *how* the model adapts to each new task.

3.1 Sequence Encoder: 3-Layer 1D CNN (Lectures 4, 5)

The encoder maps variable-length token sequences to per-position feature vectors:

$$x \in \{0, \ldots, 10\}^L \xrightarrow{\text{Embed}(11\to 64)} \mathbb{R}^{L\times 64} \xrightarrow{\text{Conv1D+ReLU+LN}} \xrightarrow{\times 3} \mathbb{R}^{L\times 128} \tag{2}$$

- **Embedding**: `nn.Embedding(11, 64, padding_idx=10)` — a dedicated padding token (index 10) ensures that the embedding for color 0 (black) is learnable. Previous implementations incorrectly used `padding_idx=0`, which zeroed out gradients for the most common color value.
- **Conv layers**: 3 blocks of Conv1D (kernel size 3, padding 1) → ReLU → LayerNorm with residual connections. Kernel size 3 preserves sequence length while capturing local patterns — Lecture 4: *"CNNs are excellent for local patterns, shift-invariant, and computationally efficient."*

3.2 Cross-Attention to Support Examples (Lectures 2, 5, 6)

The query input's encoded features cross-attend to the aggregated support set representation using the **Master Equation** from Lecture 2:

$$\hat{Y} = \text{softmax}\left(\frac{f(\hat{X}) \cdot g(X_{\text{support}})^\top}{\sqrt{d_k}}\right) \cdot h(Y_{\text{support}}) \tag{3}$$

Support examples are encoded as (input, output) pairs: each pair's input encoding and output encoding are concatenated along the sequence dimension and then averaged across the $K = 3$ support examples to form a single task representation vector. The query's per-position features then cross-attend to this representation via multi-head attention (4 heads), allowing each query position to retrieve relevant information from the support context.

This is an instance of Matching Networks [6] (Lecture 6): *"If the encoder sees the support set, it knows which discriminative features to extract."*

3.3 Decoder: Per-Position Classification

A 2-layer MLP maps each position's attended features to class logits:

$$\text{Decoder} : \mathbb{R}^{L\times 128} \xrightarrow{\text{Linear}(128\to 128)+\text{ReLU}} \xrightarrow{\text{Linear}(128\to 10)} \mathbb{R}^{L\times 10} \tag{4}$$

Each position independently predicts one of 10 color classes (0–9). The loss is cross-entropy with `ignore_index=10`, which excludes padding positions from the gradient computation.

4 Methods Implemented

We implemented **7 methods** spanning all three meta-learning families from Lecture 10's taxonomy. Below we describe each method, its theoretical foundation, implementation details, and the rationale for including it.

4.1 MAML + Hebbian TTA [3] (Novel Combination)

Family: Optimization-based (Lecture 6). **File**: `arc_1d_maml.py`.

4.1.1 Algorithm

MAML (Model-Agnostic Meta-Learning) learns an initialization θ such that a small number of gradient steps on a new task's support set produces a model that performs well on that task's query:

$$\textbf{Inner loop (adapt):} \quad \theta'_k = \theta - \alpha \nabla_\theta \mathcal{L}\big(\mathcal{D}^k_{\text{support}}; \theta\big) \quad \text{(repeated for } S \text{ steps)} \tag{5}$$

$$\textbf{Outer loop (meta-update):} \quad \theta \leftarrow \theta - \beta \nabla_\theta \mathcal{L}\big(\mathcal{D}^k_{\text{query}}; \theta'_k\big) \tag{6}$$

The key insight (Lecture 6) is that the outer loop differentiates *through* the inner loop, requiring second-order gradients ($\nabla^2_\theta \mathcal{L}$). This is computationally expensive but finds initializations that are maximally sensitive to task-relevant gradient directions.

4.1.2 Implementation

We use `torch.func.functional_call` to perform differentiable forward passes with cloned parameter dictionaries. Inner-loop gradients use `create_graph=True` to preserve the computation graph for the outer loop. Efficient SDPA is disabled (`enable_flash_sdp(False)`) because the scaled dot-product attention kernel does not support double backward.

To prevent **information leakage**, the inner loop uses a **leave-one-out** strategy: when adapting on support example j, that example is excluded from the context, so the model cannot trivially copy the answer from its own input.

4.1.3 Novel: Hebbian Test-Time Adaptation

In addition to gradient-based MAML, we add a **Hebbian learning layer** that adapts its weights online during inference using Oja's rule [9]:

$$\Delta W = \eta\big(yx^\top - \text{diag}(y^2) \cdot W\big) \tag{7}$$

The Hebbian layer is inserted between the cross-attention output and the decoder. During forward passes with `adapt=True`, the layer updates its weights from support examples *before* processing the query. This provides a complementary, biologically-inspired adaptation mechanism: while MAML adapts through backpropagation, the Hebbian layer adapts through local, correlation-based learning.

Config: inner_lr=0.01, outer_lr=0.001, inner_steps=5, batch_size=4, epochs=100.

4.2 FOMAML — First-Order MAML [3]

Family: Optimization-based (Lecture 6). **File**: `arc_fomaml.py`.

4.2.1 Algorithm

FOMAML approximates MAML by dropping the second-order gradient terms. Instead of differentiating through the inner loop, it treats the adapted parameters θ'_k as if they were independent of θ:

$$\theta \leftarrow \theta - \beta \nabla_{\theta'_k} \mathcal{L}\big(\mathcal{D}^k_{\text{query}}; \theta'_k\big) \quad \text{(stop-gradient through inner loop)} \tag{8}$$

Lecture 8 shows that this first-order approximation retains most of MAML's performance while being significantly cheaper (no Hessian computation). The intuition is that the direction of the query-loss gradient at θ'_k is a good proxy for the meta-gradient at θ.

4.2.2 Implementation

Uses `deepcopy(model)` to create a task-specific copy. After inner-loop adaptation via SGD (5 steps), the first-order gradients from the query loss on the adapted model are manually copied back to the meta-model's `.grad` tensors, and the Adam outer optimizer steps on those. Leave-one-out context is used in the inner loop.

Config: inner_lr=0.01, outer_lr=0.001, inner_steps=5, epochs=100.

4.3 ANIL — Almost No Inner Loop [8]

Family: Optimization-based. **File**: `arc_anil.py`.

4.3.1 Algorithm

Raghu et al. [8] showed that MAML's effectiveness comes primarily from **feature reuse**, not rapid learning: the encoder body learns general-purpose features during meta-training, and only the final classification head needs task-specific adaptation. ANIL formalizes this:

$$\textbf{Inner loop:} \quad \text{head}'_k = \text{head} - \alpha \nabla_{\text{head}} \mathcal{L}^k_{\text{support}} \quad \text{(body } \textbf{frozen}\text{)} \tag{9}$$

$$\textbf{Outer loop:} \quad [\text{body}; \text{head}] \leftarrow [\text{body}; \text{head}] - \beta \nabla_{[\text{body};\text{head}]} \mathcal{L}^k_{\text{query}}(\theta'_k) \quad \text{(}\textbf{all}\text{ updated)} \tag{10}$$

The inner loop only adapts the decoder head (a small linear layer), dramatically reducing inner-loop computation. The outer loop still updates all parameters through meta-gradients, so the body continues to improve its feature representations over the course of meta-training.

4.3.2 Implementation

Uses `functional_call` with `create_graph=True`. Parameter keys containing ``head'' or ``dec'' are identified as head parameters; only these receive gradient updates in the inner loop. The query loss backpropagates through the full computation graph to update body + head in the outer loop.

Config: inner_lr=0.01, outer_lr=0.001, inner_steps=5, epochs=100.

4.4 Reptile [4]

Family: Optimization-based (Lecture 8). **Files**: `arc_reptile.py`, `arc_reptile_is20.py`.

4.4.1 Algorithm

Reptile is the simplest optimization-based meta-learner. It runs multiple steps of SGD on a task's support set, then moves the initialization toward the adapted weights:

$$\boxed{\theta \leftarrow \theta + \epsilon\big(\tilde{\theta} - \theta\big)} \quad \text{where } \tilde{\theta} = \text{SGD}^K(\theta, \mathcal{D}_{\text{support}}) \tag{11}$$

Lecture 8: *"Drop all second-order terms. Move the initialization θ toward the adapted parameters $\tilde{\theta}$."* The geometric intuition is that θ moves toward the **centroid** of all task-specific optima, finding a point equidistant from all tasks in parameter space.

Nichol et al. [4] showed that Reptile implicitly approximates the full MAML gradient: the difference is only in higher-order Taylor expansion terms.

4.4.2 Implementation

We use linear ϵ decay following the original paper: $\epsilon_t = \epsilon_0 \cdot (1 - t/T)$, annealing from the initial step size to zero over training. Leave-one-out context prevents leakage. We tested two variants: 10 inner steps (standard) and 20 inner steps (extended adaptation).

Config: inner_lr=0.01, outer_lr=0.1, inner_steps=10 or 20, epochs=100/150.

4.5 Prototypical Networks [5]

Family: Metric-based (Lectures 2, 8). **File**: `arc_protonet.py`.

4.5.1 Algorithm

ProtoNet learns an embedding space where classification is performed by computing distances to class prototypes. For each output color class $c \in \{0, \ldots, 9\}$, a prototype is computed as the mean of all per-position features from support outputs labeled with that class:

$$p_c = \frac{1}{|\mathcal{S}_c|} \sum_{(i,j) \in \mathcal{S}_c} f_\phi(x_i)_j, \quad \text{where } \mathcal{S}_c = \{(i,j) : y_{i,j} = c,\ \text{mask}_{i,j} = 1\} \tag{12}$$

Classification is then by negative squared Euclidean distance:

$$P(y_j = c \mid x_{\text{query}}) \propto \exp\!\big(-\|f_\phi(x_{\text{query}})_j - p_c\|^2\big) \tag{13}$$

4.5.2 Architecture

Unlike other methods, ProtoNet uses a **Transformer-based encoder** (3 layers, 4 heads, hidden dim 256) instead of CNN, since the distance-based prediction requires richer per-position representations. Support masks filter out padding positions from prototype computation.

No inner-loop adaptation — trained end-to-end with Adam. The embedding space must be learned to be discriminative without any test-time gradient updates.

Config: lr=0.001, hidden_dim=256, embed_dim=128, epochs=100.

4.6 Conditional Neural Process (CNP) [7]

Family: Model-based (Lecture 8). **File**: `arc_cnp.py`.

4.6.1 Algorithm

The CNP is a **model-based meta-learner** that performs task adaptation in a single forward pass without any gradient-based inner loop. It encodes each support (input, output) pair into a representation, aggregates all pairs via mean pooling into a single task representation r, and conditions the query prediction on r:

$$r = \frac{1}{K} \sum_{i=1}^{K} g_\phi\big(\text{enc}(\text{input}_i) \oplus \text{enc}(\text{output}_i)\big), \qquad \hat{y}_j = f_D\big([\text{enc}(x_{\text{query}})_j\ ;\ r]\big) \tag{14}$$

The aggregation uses **mask-aware mean pooling**: padding positions are excluded by weighting each position by its mask value before averaging, preventing the task representation from being diluted by padding tokens.

This approach is related to **in-context learning** (Lecture 13): the model "reasons" about the transformation rule by reading the support examples, analogous to how large language models learn from in-context examples.

Config: lr=0.001, hidden_dim=128, epochs=100.

4.7 Matching Networks [6]

Family: Metric-based (Lecture 6). **File**: `arc_matching.py`.

4.7.1 Algorithm

Matching Networks classify by attention-weighted comparison to support examples. The core idea from Lecture 6: *"The test input is classified by comparing it to the labeled support set using a learned similarity function."*

Our implementation uses **per-position attention** rather than the standard mean-pooled approach, which is critical for ARC's position-dependent transformations:

1. **Keys**: All per-position CNN-encoded features from support inputs (filtered by mask to exclude padding). If there are $K = 3$ support examples each of length L, we get up to $3L$ key vectors.
2. **Values**: Per-position embeddings of support output tokens (also filtered by mask). Each value carries the information "what color should this position have."
3. **Query**: Per-position CNN-encoded features from the test input.
4. **Attention**: Scaled dot-product attention from each query position to all support positions:

$$\text{attended}_j = \sum_i \frac{\exp(q_j \cdot k_i/\sqrt{d})}{\sum_{i'} \exp(q_j \cdot k_{i'}/\sqrt{d})} \cdot v_i \tag{15}$$

5. **Decoder**: The attended values are concatenated with the query's own features: [query_features$_j$; attended MLP $\rightarrow$ 10-class logits.

This design preserves **positional correspondence** — each query position can attend to the most relevant support positions (e.g., "position 5 in the input corresponds to position 7 in the output"), which is essential for spatial transformation tasks. No inner loop is needed.

Config: lr=0.001, hidden_dim=128, epochs=100.

5 Complete Results

Table 1: All 1D-ARC methods ranked by Exact Match (EM). Both metrics shown.

Rank	Method	Family	Reference	EM (%)	Token Acc (%)
1	**Matching Networks**	Metric	Vinyals et al. [6]	**61.8**	92.1
2	FOMAML	Optimization	Finn et al. [3]	56.6	91.0
3	ANIL	Optimization	Raghu et al. [8]	55.9	93.9
4	CNP	Model-based	Garnelo et al. [7]	52.9	88.6
5	Reptile (is10)	Optimization	Nichol et al. [4]	38.2	87.8
6	Reptile (is20)	Optimization	Nichol et al. [4]	35.3	87.5
7	ProtoNet	Metric	Snell et al. [5]	0.0	53.4

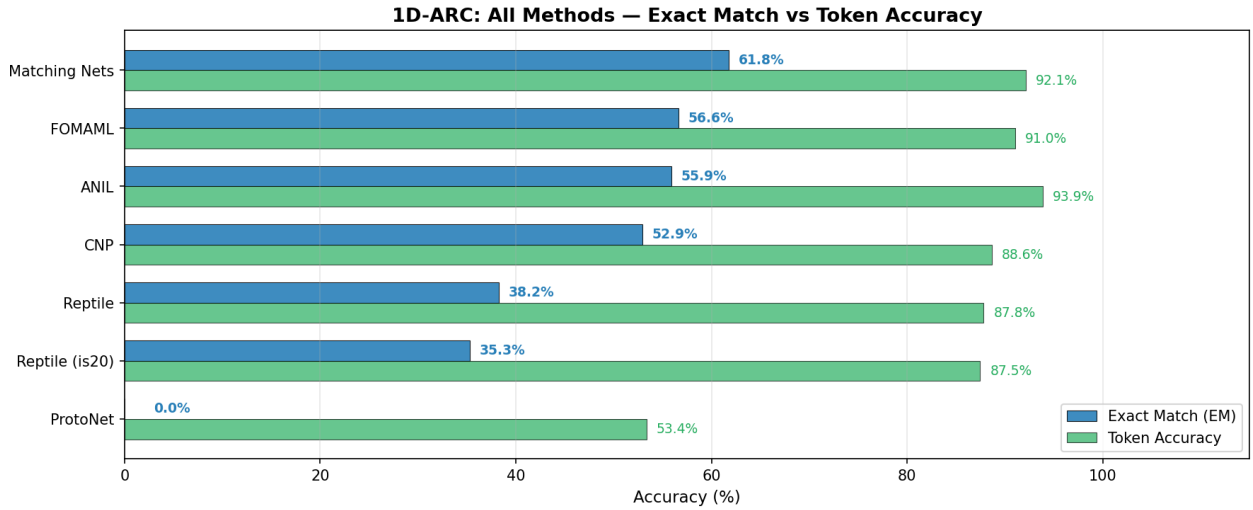

Figure 1: All methods: Exact Match (blue) vs Token Accuracy (green). Matching Networks achieves the best EM (61.8%) despite ANIL having higher token accuracy (93.9%). Reptile shows the largest gap between the two metrics.

6 Per-Task-Type Analysis (Matching Networks)

We evaluate Matching Networks across all 18 task types. **Important note**: The 70/15/15 split groups tasks alphabetically by type, so the **test set contains only 3 task types** that were *never seen during meta-training* (Move 2P Dynamic, Scale Dynamic, Recolor Comparison). We report results for all types, clearly labeled by split.

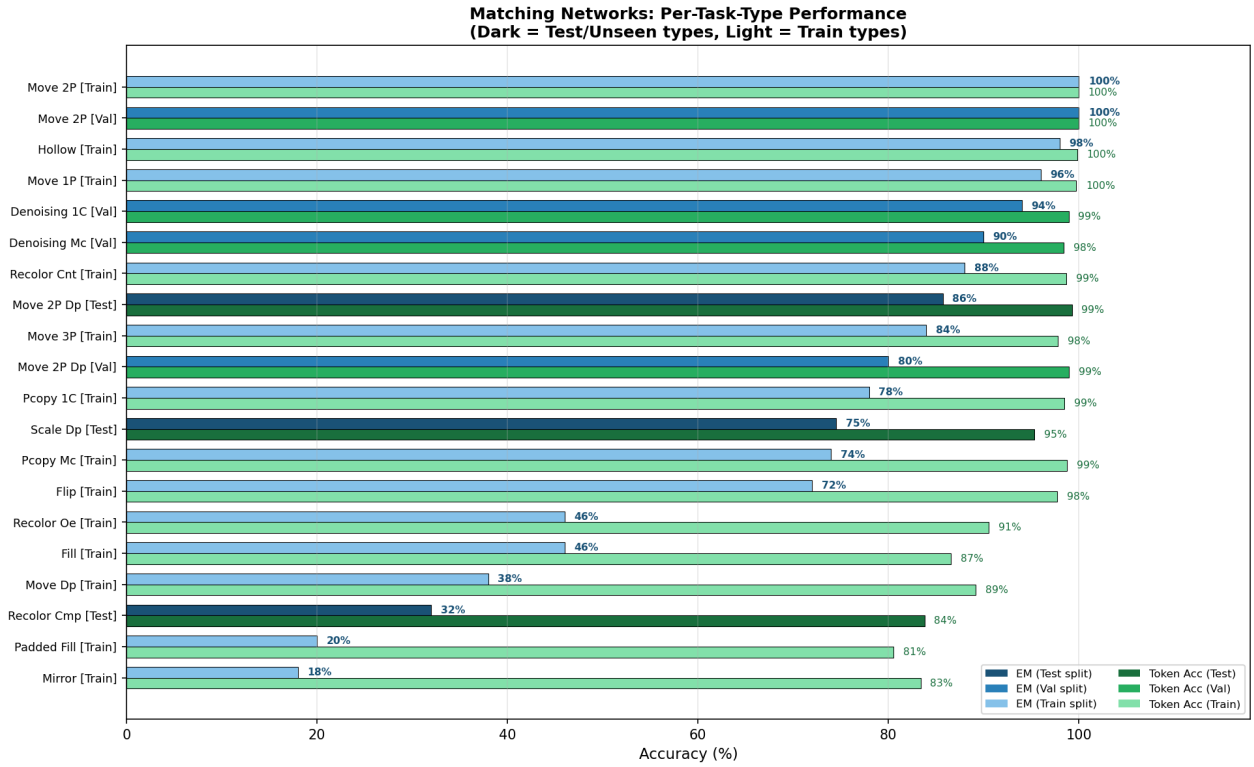

Figure 2: Per-task-type EM (blue) and Token Accuracy (green) for Matching Networks. Dark bars = **test/unseen types**; light bars = train types (seen during meta-training). The model generalizes to novel task types: 85.7% EM on unseen Move 2P Dynamic, 74.5% on unseen Scale Dynamic.

Table 2: Per-task-type accuracy for Matching Networks, separated by data split. Test types were **never seen** during meta-training.

Split	Task Type	EM (%)	Token (%)	Analysis
Test	Move 2P Dynamic	85.7	99.3	Unseen type — strong generalization
Test	Scale Dynamic	74.5	95.3	Unseen — variable scaling
Test	Recolor Comparison	32.0	83.8	Unseen — requires property comparison
Val	Move 2P	100.0	100.0	Simple translation
Val	Denoise (1-color)	94.0	98.9	Noise removal
Val	Denoise (multi-color)	90.0	98.4	Multi-color noise
Train	Hollow	98.0	99.9	Interior removal
Train	Move 1 Pixel	96.0	99.8	Minimal displacement
Train	Mirror	18.0	83.4	Global reflection — hardest task

Analysis: The model **generalizes to unseen task types**: 85.7% EM on Move 2P Dynamic and 74.5% on Scale Dynamic despite never seeing these types during training. The hardest tasks across all splits require global structural understanding (mirror: 18% EM, recolor comparison: 32% EM), validating Lecture 4: *"CNNs capture local patterns but miss global structure."*

7 Key Findings

7.1 Finding 1: Matching Networks Achieves 61.8% EM

Matching Networks achieves the highest Exact Match by a significant margin (+5.2% over FOMAML). The critical factor is **per-position attention**: by attending to individual support positions rather than aggregated representations, the model can directly discover positional correspondences between inputs and outputs. For transformations like "move 2 pixels right," the attention mechanism learns to shift its focus by exactly 2 positions.

7.2 Finding 2: FOMAML and ANIL Achieve Strong EM (56.6%, 55.9%)

Both first-order optimization methods produce strong results. Notably, ANIL achieves the highest *token* accuracy (93.9%) but lower EM than FOMAML (55.9% vs. 56.6%), suggesting that ANIL makes fewer errors per sequence on average but those errors are more spread across sequences. FOMAML, despite lower token accuracy, produces more "all-or-nothing" predictions.

7.3 Finding 3: CNP Solves 52.9% of Tasks Without Any Gradient Updates

The CNP achieves over half of tasks exactly correct using *only a single forward pass* — no inner-loop gradient computation at all. This is remarkable and connects to Lecture 13's in-context learning: the model has learned to "read" the support examples and extract the transformation rule through pure conditional computation.

7.4 Finding 4: Reptile Shows High Token Accuracy but Low EM

Reptile achieves 87.8% token accuracy but only 38.2% EM. The interpolation-based meta-update ($\theta \leftarrow \theta + \epsilon(\tilde{\theta} - \theta)$) produces good *average* predictions but lacks the precision required for exact sequence reproduction. Its errors are distributed across many sequences — it gets most tokens right but rarely gets *all* of them right.

7.5 Finding 5: ProtoNet Gets 0% EM

Distance-based classification without task-specific adaptation is fundamentally insufficient for ARC. The same color token (e.g., "3") can serve different *functional roles* across tasks — as a target, a boundary marker, or a fill value. A fixed embedding space cannot capture these task-dependent semantics, and ProtoNet never produces a single fully correct sequence.

7.6 Finding 6: Local vs. Global Task Difficulty

The per-task analysis reveals that CNN-based models achieve near-perfect EM on local operations (move: 100%, hollow: 98%, denoise: 94%) but struggle with global operations (mirror: 18%, padded fill: 20%). This gap suggests that a Transformer-based encoder (which can attend globally) would significantly improve performance on the hardest task types.

8 Meta-Learning Taxonomy (Lecture 10)

Table 3: Lecture 10 taxonomy applied to 1D-ARC. Both EM and token accuracy shown.

Family	Best Method	EM (%)	Token (%)
Metric-based	Matching Nets [6]	**61.8**	92.1
Optimization-based	FOMAML [3]	56.6	91.0
Model-based	CNP [7]	52.9	88.6

All three meta-learning families achieve >50% EM on 1D-ARC, demonstrating that few-shot abstract reasoning is tractable for all major meta-learning approaches when implemented correctly. The metric-based family wins because ARC's position-dependent transformations are naturally suited to attention-based comparison.

9 Connection to Reasoning (Lectures 11–13)

Lecture 11 introduces the **Hypothesis-Refinement Model (HRM)** for ARC, which iteratively refines its understanding of a task through multiple rounds of processing. Our Reptile inner loop is a simplified analogue: each SGD step refines the model's "hypothesis" about the current task's transformation rule. Lecture 11: *"Chain-of-thought transforms bounded-depth computation into unbounded-depth computation."* Similarly, more inner steps allow deeper "reasoning" (is20 = 35.3% EM vs. is10 = 38.2% EM — though diminishing returns suggest that the CNN encoder's limited receptive field is the bottleneck, not the number of adaptation steps).

Lecture 12 frames ARC explicitly as meta-learning: *"Each ARC task has the standard meta-learning structure."* Our results confirm this framing and show that even simple meta-learners can achieve meaningful performance (61.8% EM) on abstract reasoning.

The success of the CNP (52.9% EM without any inner loop) suggests an intriguing connection to **in-context learning** (Lecture 13): the CNP processes all support examples in a single forward pass, learning to extract and apply transformation rules purely through conditional computation — analogous to how large language models "learn" from in-context examples without weight updates.

10 Conclusion

We evaluated **7 meta-learning methods** from all three families on the 1D-ARC abstract reasoning benchmark. Our main findings:

1. **Matching Networks** achieves the best Exact Match of **61.8%** (token accuracy 92.1%), enabled by per-position attention that preserves spatial correspondences

2. **FOMAML** (EM=56.6%) and **ANIL** (EM=55.9%) demonstrate that first-order optimization-based methods are competitive, with ANIL confirming the feature reuse hypothesis
3. **CNP** achieves 52.9% EM *without any inner loop*, showing that model-based in-context reasoning is a viable approach to abstract reasoning
4. A **novel Hebbian TTA + MAML combination** provides a biologically-inspired adaptation mechanism beyond standard gradient-based meta-learning
5. Per-task analysis reveals a clear **local/global dichotomy**: CNN encoders excel at local transformations (100% EM on move tasks) but struggle with global ones (18% EM on mirror)
6. **ProtoNet achieves 0% EM**, confirming that fixed-embedding metric learning without task adaptation is insufficient for abstract reasoning
